## Abstract

Density functional theory (DFT) calculations were used to explore the Au(I)-catalyzed selective [4+1] annulations of cyclopropyl- and H-substituted 1,4-diyn-3-ols with isoxazole. The results indicated that the N-nucleophilic attack of isoxazole favors the  $\pi$ -non-phenylalkyne position of 1,4-diyn-3-ols, which can be attributed to a smaller steric hindrance involved as compared to the attack at the phenylalkyne position. After the nucleophilic attack, instead of obtaining the  $\alpha$ -hydroxy gold carbene intermediate proposed experimentally, a concerted three-step forward product by isoxazole O-N cleavage, 1,2-phenylalkyne shift and the hydroxyl H shift was identified as the key intermediate, for the reaction proceeding either via an Au-assisted C=C double-bond rotation to produce the *Z*-isomeric enone or via two different Au-assisted C=C rotations to furnish the *E*-configured enone depending on the substituents used. Further theoretical investigations indicated that the chemoselective step is the nucleophilic cyclization but not the C=C double-bond rotation. The chemoselective preference for the *Z*-configured product using the cyclopropyl substituent was attributed to two factors: i) the additional O $\cdots$ H—N hydrogen bonding interaction stabilizes the rate-determining cyclization TS leading to the *Z*-product, and ii) further *Z-E* product-isomerization is blocked due to significant structural deformation being involved. In contrast, using the H substituent results in a reversed chemoselectivity with exclusive formation of the *E*-configured enones, which is closely related to the smaller entropy effects involved.

## 1. Introduction

Pyrrole frameworks are significant core structures for numerous bioactive and natural products [1-4], which has stimulated the development of new synthetic strategies for their formation. Gold-catalyzed annulations of unsaturated hydrocarbons with N, O-containing nucleophiles have emerged as powerful tools to access highly functionalized pyrrole heterocycles [5-11]. As a result, these reactions have attracted significant attention and have been extensively investigated. A series of gold-catalyzed [3+2]-annulations of isoxazoles or benzisoxazoles with ynamides have been evaluated by several research groups, including Ye [12-14] and Hashmi [15-16], etc. In addition, other N,O heterocyclic nucleophilicities, such as 1,4,2-dioxazoles [17], 1,2,4-oxadiazoles [18] and 4,5-dihydro-1,2,4-oxadiazoles [19], have been shown to participate in these catalytic annulations with ynamides. Apart from electron-rich ynamides, the electron-deficient propiolates have been developed for the gold-catalyzed [4+1]-annulations of isoxazoles [20, 21]. However, in contrast to the annulations with reactive ynamides and propiolates, the corresponding reactions with unactivated alkynes are rarely investigated.

Recently, Liu and co-workers successfully described the gold-catalyzed [4+1]-annulation of isoxazoles or benzisoxazoles [22], in which inactive 1,4-diyn-3-ols are employed as the electrophilic reactants. These operationally simple reactions feature broad substrate scope and exhibit extraordinary chemoselectivity and regioselectivity. Scheme 1 displays the representative gold (I)-catalyzed annulations developed by Liu's group [22]. With  $\text{LAuCl/AgOTf}$  (10 mol %) ( $\text{L} = \text{IPr}$ ) in hot dichloroethane (DCE) at  $80^\circ\text{C}$ , the cyclopropyl-substituted 1,4-diyn-3-ol ( $\text{R} = \text{cyclopropyl}$ ), **1A**, produces the *Z*-configured pyrrolyl N-enone **<sup>Z</sup>P<sub>a</sub>** in a high yield. However, under the identical catalytic conditions, replacing the cyclopropyl group in **1A** by a hydrogen atom (the

substrate is denoted as **2A**) results in a different chemoselectivity: the final product being the *E*-configured enone **<sup>E</sup>P<sub>b</sub>** with an isolated yield of 64%.

**Scheme 1.** Au(I)-catalyzed chemoselective [4+1] annulations of representative nonsymmetric 1,4-diyn-3-ols (**A**) with isoxazole (**B**) reported by Liu and co-workers [22].

To account for these annulation reactions, plausible mechanistic pathways are proposed by Liu et al. [22] and shown in Scheme 2 with the representative substrates **1A** and **2A**, respectively. For the reaction of **1A**, the LAu<sup>+</sup>  $\pi$ -coordinates regioselectivity with the phenylalkyne over the cyclopropylalkyne of **1A**, followed by N-nucleophilic attack of the isoxazole **B** at C<sup>1</sup>, producing species **2**. The isoxazole N-O cleavage of **2** then occurs to afford  $\alpha$ -hydroxy iminogold carbene intermediate **3**. Subsequently, 1,2-alkyne migration and protodeauration furnishes the Au- $\pi$ -3-yn-1-imine adduct **5**, from which **<sup>Z</sup>P<sub>a</sub>** is ultimately produced with the dissociation of the active LAu<sup>+</sup> catalyst. With the system starting with **2A**, Liu and co-workers postulated that the reaction proceeds via a similar pathway, i.e., LAu<sup>+</sup>  $\pi$ -coordination with the terminal alkyne, nucleophilic attack of **B**, isoxazole N-O cleavage, the 1,2-alkyne migration and protodeauration, resulting in the *Z*-configured enone **8**. Liu postulates that the *E*-configured isomer **<sup>E</sup>P<sub>b</sub>** is then formed through a facile C=C double bond rotation.

**Scheme 2.** Postulated pathways proposed by Liu's group [22] for the Au(I)-catalyzed

The reaction scheme illustrates the synthesis of 2-phenyl-2,3-bis(tricyclopropylmethyl)pyridine (2' AuL) from 2-phenyl-2,3-bis(tricyclopropylmethyl)pyridine (2 AuL). The scheme is divided into two main pathways, one for R = cyclopropylmethyl (blue) and one for R = H (red).

**Blue Pathway (R = cyclopropylmethyl):**

- Starting material **2 AuL** (2-phenyl-2,3-bis(tricyclopropylmethyl)pyridine) is shown in a blue box.
- Reaction with **AuL** (R = cyclopropylmethyl) leads to intermediate **1** (2-phenyl-2,3-bis(tricyclopropylmethyl)pyridine-1-ylidene-gold complex).
- Intermediate **1** reacts with **B** (cyclopropylmethyl) to form intermediate **2** (2-phenyl-2,3-bis(tricyclopropylmethyl)pyridine-1,2-diylidene-gold complex).
- Intermediate **2** reacts with **B** to form intermediate **3** (2-phenyl-2,3-bis(tricyclopropylmethyl)pyridine-1,2,3-triylidene-gold complex).
- Intermediate **3** reacts with **B** to form intermediate **4** (2-phenyl-2,3-bis(tricyclopropylmethyl)pyridine-1,2,3,4-tetraylidene-gold complex).
- Intermediate **4** reacts with **B** to form intermediate **5** (2-phenyl-2,3-bis(tricyclopropylmethyl)pyridine-1,2,3,4,5-pentaylidene-gold complex).
- Intermediate **5** reacts with **B** to form intermediate **6** (2-phenyl-2,3-bis(tricyclopropylmethyl)pyridine-1,2,3,4,5,6-hexaylidene-gold complex).
- Intermediate **6** reacts with **B** to form intermediate **7** (2-phenyl-2,3-bis(tricyclopropylmethyl)pyridine-1,2,3,4,5,6,7-heptylidene-gold complex).
- Intermediate **7** reacts with **B** to form intermediate **8** (2-phenyl-2,3-bis(tricyclopropylmethyl)pyridine-1,2,3,4,5,6,7,8-octaylidene-gold complex).
- Intermediate **8** reacts with **B** to form intermediate **9** (2-phenyl-2,3-bis(tricyclopropylmethyl)pyridine-1,2,3,4,5,6,7,8,9-nonylidene-gold complex).
- Intermediate **9** reacts with **B** to form intermediate **10** (2-phenyl-2,3-bis(tricyclopropylmethyl)pyridine-1,2,3,4,5,6,7,8,9,10-decaylidene-gold complex).
- Intermediate **10** reacts with **B** to form intermediate **11** (2-phenyl-2,3-bis(tricyclopropylmethyl)pyridine-1,2,3,4,5,6,7,8,9,10,11-undecaylidene-gold complex).
- Intermediate **11** reacts with **B** to form intermediate **12** (2-phenyl-2,3-bis(tricyclopropylmethyl)pyridine-1,2,3,4,5,6,7,8,9,10,11,12-dodecaylidene-gold complex).
- Intermediate **12** reacts with **B** to form intermediate **13** (2-phenyl-2,3-bis(tricyclopropylmethyl)pyridine-1,2,3,4,5,6,7,8,9,10,11,12,13-tridecaylidene-gold complex).
- Intermediate **13** reacts with **B** to form intermediate **14** (2-phenyl-2,3-bis(tricyclopropylmethyl)pyridine-1,2,3,4,5,6,7,8,9,10,11,12,13,14-tetradecaylidene-gold complex).
- Intermediate **14** reacts with **B** to form intermediate **15** (2-phenyl-2,3-bis(tricyclopropylmethyl)pyridine-1,2,3,4,5,6,7,8,9,10,11,12,13,14,15-pentadecaylidene-gold complex).
- Intermediate **15** reacts with **B** to form intermediate **16** (2-phenyl-2,3-bis(tricyclopropylmethyl)pyridine-1,2,3,4,5,6,7,8,9,10,11,12,13,14,15,16-hexadecaylidene-gold complex).
- Intermediate **16** reacts with **B** to form intermediate **17** (2-phenyl-2,3-bis(tricyclopropylmethyl)pyridine-1,2,3,4,5,6,7,8,9,10,11,12,13,14,15,16,17-heptadecaylidene-gold complex).
- Intermediate **17** reacts with **B** to form intermediate **18** (2-phenyl-2,3-bis(tricyclopropylmethyl)pyridine-1,2,3,4,5,6,7,8,9,10,11,12,13,14,15,16,17,18-octadecaylidene-gold complex).
- Intermediate **18** reacts with **B** to form intermediate **19** (2-phenyl-2,3-bis(tricyclopropylmethyl)pyridine-1,2,3,4,5,6,7,8,9,10,11,12,13,14,15,16,17,18,19-nonadecaylidene-gold complex).
- Intermediate **19** reacts with **B** to form intermediate **20** (2-phenyl-2,3-bis(tricyclopropylmethyl)pyridine-1,2,3,4,5,6,7,8,9,10,11,12,13,14,15,16,17,18,19,20-eicadecaylidene-gold complex).
- Intermediate **20** reacts with **B** to form intermediate **21** (2-phenyl-2,3-bis(tricyclopropylmethyl)pyridine-1,2,3,4,5,6,7,8,9,10,11,12,13,14,15,16,17,18,19,20,21-tricadecaylidene-gold complex).
- Intermediate **21** reacts with **B** to form intermediate **22** (2-phenyl-2,3-bis(tricyclopropylmethyl)pyridine-1,2,3,4,5,6,7,8,9,10,11,12,13,14,15,16,17,18,19,20,21,22-tetracadecaylidene-gold complex).
- Intermediate **22** reacts with **B** to form intermediate **23** (2-phenyl-2,3-bis(tricyclopropylmethyl)pyridine-1,2,3,4,5,6,7,8,9,10,11,12,13,14,15,16,17,18,19,20,21,22,23-pentacadecaylidene-gold complex).
- Intermediate **23** reacts with **B** to form intermediate **24** (2-phenyl-2,3-bis(tricyclopropylmethyl)pyridine-1,2,3,4,5,6,7,8,9,10,11,12,13,14,15,16,17,18,19,20,21,22,23,24-hexacadecaylidene-gold complex).
- Intermediate **24** reacts with **B** to form intermediate **25** (2-phenyl-2,3-bis(tricyclopropylmethyl)pyridine-1,2,3,4,5,6,7,8,9,10,11,12,13,14,15,16,17,18,19,20,21,22,23,24,25-heptacadecaylidene-gold complex).
- Intermediate **25** reacts with **B** to form intermediate **26** (2-phenyl-2,3-bis(tricyclopropylmethyl)pyridine-1,2,3,4,5,6,7,8,9,10,11,12,13,14,15,16,17,18,19,20,21,22,23,24,25,26-octacadecaylidene-gold complex).
- Intermediate **26** reacts with **B** to form intermediate **27** (2-phenyl-2,3-bis(tricyclopropylmethyl)pyridine-1,2,3,4,5,6,7,8,9,10,11,12,13,14,15,16,17,18,19,20,21,22,23,24,25,26,27-nonacadecaylidene-gold complex).
- Intermediate **27** reacts with **B** to form intermediate **28** (2-phenyl-2,3-bis(tricyclopropylmethyl)pyridine-1,2,3,4,5,6,7,8,9,10,11,12,13,14,15,16,17,18,19,20,21,22,23,24,25,26,27,28-decacadecaylidene-gold complex).
- Intermediate **28** reacts with **B** to form intermediate **29** (2-phenyl-2,3-bis(tricyclopropylmethyl)pyridine-1,2,3,4,5,6,7,8,9,10,11,12,13,14,15,16,17,18,19,20,21,22,23,24,25,26,27,28,29-undecadecaylidene-gold complex).
- Intermediate **29** reacts with **B** to form intermediate **30** (2-phenyl-2,3-bis(tricyclopropylmethyl)pyridine-1,2,3,4,5,6,7,8,9,10,11,12,13,14,15,16,17,18,19,20,21,22,23,24,25,26,27,28,29,30-dodecadecaylidene-gold complex).
- Intermediate **30** reacts with **B** to form intermediate **31** (2-phenyl-2,3-bis(tricyclopropylmethyl)pyridine-1,2,3,4,5,6,7,8,9,10,11,12,13,14,15,16,17,18,19,20,21,22,23,24,25,26,27,28,29,30,31-tridecadecaylidene-gold complex).
- Intermediate **31** reacts with **B** to form intermediate **32** (2-phenyl-2,3-bis(tricyclopropylmethyl)pyridine-1,2,3,4,5,6,7,8,9,10,11,12,13,14,15,16,17,18,19,20,21,22,23,24,25,26,27,28,29,30,31,32-tetradekadecaylidene-gold complex).
- Intermediate **32** reacts with **B** to form intermediate **33** (2-phenyl-2,3-bis(tricyclopropylmethyl)pyridine-1,2,3,4,5,6,7,8,9,10,11,12,13,14,15,16,17,18,19,20,21,22,23,24,25,26,27,28,29,30,31,32,33-pentadekadecaylidene-gold complex).
- Intermediate **33** reacts with **B** to form intermediate **34** (2-phenyl-2,3-bis(tricyclopropylmethyl)pyridine-1,2,3,4,5,6,7,8,9,10,11,12,13,14,15,16,17,18,19,20,21,22,23,24,25,26,27,28,29,30,31,32,33,34-hexadekadecaylidene-gold complex).
- Intermediate **34** reacts with **B** to form intermediate **35** (2-phenyl-2,3-bis(tricyclopropylmethyl)pyridine-1,2,3,4,5,6,7,8,9,10,11,12,13,14,1

## 2. Computational Details

All DFT calculations were carried out with the Gaussian 09 version [23]. The geometries of all stationary points were fully optimized in the framework of density functional theory (DFT) at the B3LYP level [24-27], which has been shown to describe Au-catalyzed and other transition-metal-catalyzed organometallic systems reasonably well [28-33]. The SDD [34, 35] basis set was chosen for Au atom whereas the 6-31g (d) basis set was used for all other atoms, including C, H, O and N atoms. All optimized stationary points were confirmed as local minima (zero imaginary frequencies) or first-order saddle points (one imaginary frequency) by performing vibrational frequencies at the same level of theory and the free energies were provided at 298.15 K. IRC [36, 37] calculations from transition states were also conducted to ensure that such structures indeed connected two relevant minima. The energies in the DCE solvent were evaluated at the M06 [38, 39] level employing a larger basis set (6-311+g(d,p)) for the non-metallic atoms and SDD basis set for Au by single-point calculations using a self-consistent reaction field (SCRF) method [40] with the PCM model [41, 42]. In addition, no entropy correction [43] is added in this paper.

## 3. Results and Discussion

### 3.1 Reactions on Cyclopropyl-Substituted Substrate 1A

#### 3.1.1 Formation Mechanism of the N-O Cleavage Intermediate

The calculated results are given in Fig. 1. Initial LAu<sup>+</sup> coordination with **1A** gives the  $\pi$ -cyclopropylalkyne coordinated adduct **IM1**, which is exergonic by 23.0 kcal/mol. From **IM1**, through **TS1-2**, the N nucleophilic attack of **B** surmounts an energy requirement of 21.2 kcal/mol to afford **IM2**. According to the proposal in Scheme 2, after the N-nucleophilic attack, the isoxazole ring-opening by N-O cleavage takes place to deliver the  $\alpha$ -hydroxy iminogold carbenoid **3**, which evolves into the final product

<sup>2</sup>P<sub>a</sub>. However, our calculated results indicate that the proposed species **3** is not a true local minimum on the potential energy profile, which is supported by the recent work of Ariaferd and co-workers [44]. Upon optimization, it always collapses into **IM3**, the forward product of a concerted three-step process, involving isoxazole O-N cleavage, 1,2-phenylalkyne shift and the hydroxyl H migration. The concerted step via **TS2-3** has a barrier of 11.3 kcal/mol and is exergonic by 45.5 kcal/mol relative to **IM2**. Therefore, in the following transformation, **IM3** was identified as the key intermediate to access <sup>2</sup>P<sub>a</sub>. Note that, from **IM2** to **TS2-3**, the N...O distance is elongated by 0.432 Å from 1.396 Å to 1.828 Å, while both the (hydroxyl) O...H (from 0.973 Å to 0.971 Å) and C3...C4 distance (1.543 Å to 1.471 Å) vary insignificantly. These results imply that the N-O rupture might be the main driving force for the concerted three-step process.

As indicated in Fig. 1, except for  $\pi$ -coordinating with the cyclopropylalkyne of **1A**, LAu<sup>+</sup> can  $\pi$ -interact with the phenylalkyne of **1A**, leading to **IM1'**, which, through **TS1-2'**, can be easily transformed into **IM1**. Unfortunately, the transition structure for the subsequent N-nucleophilic attack from **IM1'**, **TS1-2'**, is found to be 3.0 kcal/mol higher than **TS1-2** in free energy. The main reason lies in the steric repulsion between the cyclopropylalkyne moiety and the isoxazole ring in **TS1-2'**. The detailed discussions for the regioselectivity are collected into Supporting Information (Fig. S1).

**Fig. 1.** Calculated free energy profiles in DCE solvent for forming the N-O cleavage intermediate **IM3** from the cyclopropyl-substituted 1,4-diyne-3-ol **1A**. The relative free energies and bond distances are given in kcal/mol and Å, respectively. L = IPr

**Fig. 2.** Calculated free energy profile in DCE solvent for forming **zP<sub>a</sub>** from the N-O cleavage intermediate **IM3** established in the present work. The relative free energies and bond distances are given in kcal/mol and Å, respectively. L = IPr

### 3.1.2 $^2P_a$ Formation Mechanism Starting from **IM3**

Fig. 2 illustrates the calculated potential energy profile for  $^2P_a$  formation from **IM3**. The hydroxyl H atom in **IM3** performs a migration to the N atom, affording more stable intermediate **IM4**. The process via **TS3-4** is very facile with a barrier of 3.8 kcal/mol, which might be attributed to the  $O\cdots H\cdots N$  interaction in the transition state. In order to facilitate intramolecular N-nucleophilic attack to the  $C^5$  atom, the  $C^1=C^2$  double-bond in **IM4**, with the assistance of  $LAu^+$ , experiences a rotation to give the isomer **IM5**. The double-bond rotation is computed to have an unexpectedly low barrier of 11.7 kcal/mol, much lower than normal  $C=C$  rotation. It is seen in Fig. 2, that the  $C^1=C^2$  double bond in **IM4** has been switched to an approximately  $C^1-C^2$  single bond in **TS4-5** with a distance of 1.523 Å. Such an unexpected  $C=C$  double-bond rotation can be attributed to the presence of the  $LAu^+$  catalyst and  $sp^2$ -N atom. For the process from **IM4** to **TS4-5**, with the  $C^1=C^2$  bond being switched to a single bond, the  $C^1-N$  single bond is being switched to a double bond. Consequently, the N atom is positively charged and  $C^2$  negatively charged in **TS4-5**. The positive charge on the N atom can be effectively delocalized by the adjacent  $sp^2$ - $C^1$  atom and vinyl aldehyde group, and simultaneously, the negative charge on  $C^2$  can be stabilized by the  $LAu^+$  catalyst. As a result, **TS4-5** is low in energy and enables the  $C^1=C^2$  rotation to be readily accessible. A similar example of  $C=C$  double-bond rotation is also found in the following figures (**IM14**  $\rightarrow$  **TS14-15** in Fig. 4, **IM19**  $\rightarrow$  **TS19-20** in Fig. 5, **IM21**  $\rightarrow$  **TS21-22** and **IM23**  $\rightarrow$  **TS23-24** in Fig. 6), and other transition-metal catalyzed systems documented by several research groups [45-48] and our group [49]. From **IM5**, with  $LAu^+$  turning to  $\pi$ -coordinate towards the phenylalkyne moiety, the ring-closure process by the N-nucleophilic attack to the  $C^5$  atom occurs and provides the pyrrole cycle intermediate **IM7**. For the subsequent protodeauration, in light of the Lewis basicity of the isoxazole (**B**) N atom, we designed a stepwise isoxazole N-assisted

protodeauration to give  $^Z\mathbf{P_a}$ , which is shown in Fig. 2. The (N)H atom in  $\mathbf{IM7}$  is firstly trapped by the isoxazole N atom to give  $\mathbf{IM8}$ . Then, the trapped H atom transfers to the C(AuL) atom via  $\mathbf{TS8-}^Z\mathbf{P_a}$ , affording the final product  $^Z\mathbf{P_a}$  with the release of  $\text{LAu}^+$  and isoxazole  $\mathbf{B}$ .

**Fig. 3.** Calculated free energy profiles in DCE solvent for forming  $^Z\mathbf{P_a}$  (black line) and  $^E\mathbf{P_a}$  via  $^Z\mathbf{P_a}$  (red line), respectively. The relative free energies are given in kcal/mol. L = IPr

Once formed,  $^Z\mathbf{P_a}$ , through a formal  $\text{C}^6=\text{C}^7$  double bond rotation, possibly isomerizes into the *E*-configured enone  $^E\mathbf{P_a}$ . Therefore, the catalytic cycle leading to  $^E\mathbf{P_a}$  starting from  $^Z\mathbf{P_a}$  should also be considered. Such an analogous isomerization has been previously reported by our group [50]. In this situation, it is believed that, after  $^Z\mathbf{P_a}$  is obtained in the first catalytic cycle, the  $\text{LAu}^+$  catalyzed reaction would diverge into two competitive cycles (Fig. 3): either the annulation of  $\mathbf{1A}$  with  $\mathbf{B}$  to furnish  $^Z\mathbf{P_a}$  (black line) or the *Z-E* isomerization of  $^Z\mathbf{P_a}$  to generate  $^E\mathbf{P_a}$  (red line). It is seen from Fig. 3 that the highest stationary point resulting in  $^E\mathbf{P_a}$ ,  $\text{C}^6=\text{C}^7$  rotation transition state  $\mathbf{TS9-10}$ , is remarkably less stable than  $\mathbf{TS1-2}$  resulting in  $^Z\mathbf{P_a}$  in free energy (-64.7 vs -73.8 kcal/mol). Furthermore, the energy demand via  $\mathbf{TS9-10}$  is as high as 30.1 kcal/mol. These observations indicate

that, once formed,  $^Z\mathbf{P_a}$  is very unlikely to transform into  $^E\mathbf{P_a}$  even with  $\mathbf{1A}$  present.

### 3.2 Reactions on H-Substituted Substrate $\mathbf{2A}$ .

As mentioned in the introduction, upon replacement of the cyclopropyl substituent by a hydrogen atom, the product-selectivity switches to produce the *E*-configured enone  $^E\mathbf{P_b}$  as the sole product. Thus, further calculations are required to reveal the origin of the opposite chemoselectivity.

For the system starting with  $\mathbf{2A}$ , we initially imitated the reaction from  $\mathbf{1A}$  to perform detailed calculations for the formation of the *Z*-configured enone  $^Z\mathbf{P_b}$  and the *E*-configured enone  $^E\mathbf{P_b}$ , which are given in Fig. 4 and 5. It was found that the reaction follows a similar mechanism to the  $\mathbf{1A}$  system discussed above. Interestingly, unlike the difficulty of  $^Z\mathbf{P_a} \rightarrow ^E\mathbf{P_a}$  in Fig. 3, the transformation from  $^Z\mathbf{P_b}$  to  $^E\mathbf{P_b}$  is much easier with a barrier of 22.5 kcal/mol (the difference between **TS19-20** and **IM19** in Fig. 5). In this case, once the substrate  $\mathbf{2A}$  is used up,  $^Z\mathbf{P_b}$  would evolve into  $^E\mathbf{P_b}$  due to the stability of **TS11-12** resulting in  $^Z\mathbf{P_b}$  over **TS19-20**. In other words, the alternative pathway leading to  $^E\mathbf{P_b}$  needs to go through  $^Z\mathbf{P_b}$ . Besides, we also theoretically examined the speculation of Liu's group in Scheme 2 [22], in which the reaction proceeds via the Au- $\pi$ -3-yn-1-imine intermediate **8**, followed by a quick  $C^6=C^7$  rotation and subsequent nucleophilic cyclization, to give  $^E\mathbf{P_b}$ . Unfortunately, the energy barrier for **8** formation, 36.3 kcal/mol (the difference between **TS14'-8** and **IM14** in Fig. S6 in the Supporting Information), is very high, which is inaccessible under the given conditions. Therefore, the pathway via **8** is ruled out theoretically and subsequent evolution into  $^E\mathbf{P_b}$  from **8** was not evaluated further.

**Fig. 4.** Calculated free energy profile in DCE solvent for forming  $^Z\text{P}_b$  from the H-substituted 1,4-diyne-3-ol **2A** established in the present work. The relative free energies are given in kcal/mol. L = IPr

**Fig. 5.** Calculated free energy profiles in DCE solvent for forming  $Z_{Pb}$  (black line) and  $E_{Pb}$  via  $Z_{Pb}$  (red line), respectively. The relative free energies are given in kcal/mol. L = IPr

The mechanism in Fig. 5 indicates that the formation of  $E_{Pb}$  needs to go through  $Z_{Pb}$ . Alternatively, avoidance of the  $Z_{Pb}$  intermediate allows us to design a new mechanism leading to  $E_{Pb}$ , which also begins with **IM14** and features a double carbon-carbon double-bond rotation assisted by  $LAu^+$ . It can be seen in Fig. 6, with the coordination isomerization of **IM14**, the adduct **IM21** is formed in which the  $C^6=C^7$  bond is activated by  $LAu^+$ . The activated  $C^6=C^7$  bond then undergoes a rotation via **TS21-22**, leading to the species **IM22**. Immediately,  $LAu^+$  turns to coordinate with the  $C^1=C^2$  bond. The resultant isomer **IM23**, through **TS23-24**, performs the  $C^1=C^2$  rotation to give **IM24**, which possesses the same *E*-configured enone moiety as  $E_{Pb}$ . It is noteworthy that the rotation step has an activation barrier of 18.0 kcal/mol and results in an overall barrier of 25.6 kcal/mol (difference between **TS23-24** and **IM22**). In contrast, the barrier for the  $C^7=C^8$  rotation via **TS21-22** is 18.8 kcal/mol. Obviously, the instability of the precursor intermediate **IM23** is of importance for the difficult  $C^1=C^2$

bond rotation via **TS23-24**. To be ready for the following nucleophilic attack,  $\text{LAu}^+$  is required to activate the alkynyl moiety. Thus, the coordination isomerization of **IM24** occurs to afford **IM25**. Subsequently, similar to **IM17**  $\rightarrow$  **<sup>Z</sup>P<sub>b</sub>** in Fig. 4, the reaction proceeds via N-nucleophilic attack of the C<sup>5</sup> atom followed by a **B**-assisted H-shift, eventually providing the product **<sup>E</sup>P<sub>b</sub>** with the dissociation of  $\text{LAu}^+$ .

From the potential energy profile shown in Fig. 6, we can clearly see that the highest stationary point leading to **<sup>E</sup>P<sub>b</sub>** corresponds to **TS25-26**, which is 2.7 kcal/mol greater than **TS16-17** leading to **<sup>E</sup>P<sub>b</sub>** via **<sup>Z</sup>P<sub>b</sub>** in Fig. 5. Using the Eyring equation, a 2.7 kcal/mol energy difference gives a ratio of 99/1, demonstrating the pathway with no involvement of **<sup>Z</sup>P<sub>b</sub>** to be a preferred mechanism for **<sup>E</sup>P<sub>b</sub>** formation.

### 3.2 Origins of Substituent-Controlled Chemoselectivity

In order to better understand the origins of the different chemoselectivities resulting from the cyclopropyl and H substituents, we performed the analyses of four selectivity-determining transition states: **TS6-7** (leading to **<sup>Z</sup>P<sub>a</sub>** in Fig. 2) vs **TS33-34** (leading to **<sup>E</sup>P<sub>a</sub>** in Fig. S3, similar to the formation of **<sup>E</sup>P<sub>b</sub>** in Fig. 6), and **TS16-17** (leading to **<sup>Z</sup>P<sub>b</sub>** in Fig. 4) vs **TS25-26** (leading to **<sup>E</sup>P<sub>b</sub>** in Fig. 6), which are re-optimized with M06 functional in DCE solvent to obtain more accurate results. All of the four stationary points are related to the five-membered ring closure. The calculated results are given in Fig. 7.

For the cyclopropyl-substituted system (left column), the free energy difference ( $\Delta\Delta G$ ) between **TS33-34** and **TS6-7** is 0.9 kcal/mol, corresponding to a ratio of 82:18 for  $^Z\mathbf{P}_a/^E\mathbf{P}_a$ . Since the counterion as a formal spectator [52-54] is not considered theoretically, the result derived from our computations is in qualitative agreement with the experimental observations regarding the 10:1 ratio for IPrAuCl/AgOTf catalysis and 4:1 for IPrAuCl/AgSbF<sub>6</sub> catalysis shown in Scheme 1. To gain insight into the *Z/E* chemoselectivity, we compared the electronic energies ( $\Delta E$ , in parentheses) and entropy effects (reflected by  $-T_{298K}\Delta S$ , in brackets) of the two transition states. In comparison with the contribution of entropy effect (2.3 kcal/mol), **TS33-34** is found to have appreciably higher electronic energy than **TS6-7** (3.7 kcal/mol). Clearly, the structural stability of **TS6-7** plays a pivotal role in the selectivity preference. Furthermore, we performed the noncovalent interactions (NCIs) analyses [54, 55] to confirm the structural discrepancy of the two transition states. One can identify in Fig. 7 that a significant O $\cdots$ H—N hydrogen bonding interaction is present in **TS6-7**, but minimal interaction is observed in **TS33-34**. In summary, the O $\cdots$ H—N hydrogen bonding interaction in **TS6-7** creates an extra stabilization energy and thus results in **TS6-7** being appreciably lower in free energy than **TS33-34**.

As far as the H-substituted system is concerned, as exhibited in the right column of Fig. 7, **TS25-26** is 1.7 kcal/mol more stable than **TS16-17** in free energy. The resulting 1:94.6 ratio of the *Z/E* products is in rough accordance with the experimentally observed exclusively *E*-product [22]. We first compared the relative stability of **TS25-26** and **TS16-17** by looking at the electronic energies in parentheses. However, the given electronic energy change (2.0 kcal/mol) for the two transition states is inconsistent with the free energy difference (-1.7 kcal/mol), indicating that the structural stability is not a determining factor leading to the reversed chemoselectivity. Further

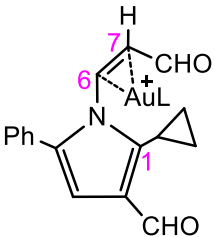

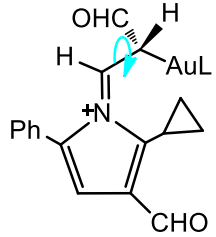

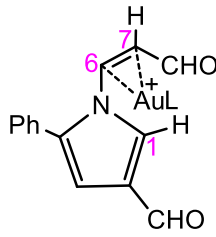

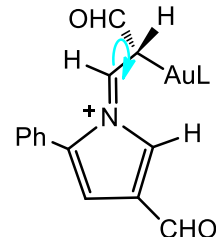

comparative analysis shows that the value of  $-T_{298K}\Delta S$  in **TS25-26** is smaller than that in **TS16-17** with a difference of -2.8 kcal/mol, which overrides the electronic energy difference of 2.0 kcal/mol. Therefore, it is believed that the larger entropy effect in **TS25-26** leads to the overall preference to the free energy over **TS16-17**. In order to obtain additional support for this deduction, we analyzed the optimized geometric structures of **TS25-26** and **TS16-17**. As highlighted with solid green oval, because of the  $O\cdots H-N$  hydrogen bonding interaction, **TS16-17** exhibits a more strained structure, thereby resulting in a smaller degree of disorder ( $\Delta S$ ). As a result, a larger value of  $-T_{298K}\Delta S$  in **TS16-17** is achieved when compared to **TS25-26**. From an entropy perspective, one can easily understand the lower free energy of **TS25-26** relative to **TS16-17**.

One the other hand, the chemoselectivity is closely related to the capability of the  $C^6=C^7$  double-bond rotation, which has an energy demand of 30.1 kcal/mol with cyclopropyl substituent (**IM9**  $\rightarrow$  **TS9-10** in Fig. 4) and 22.5 kcal/mol with H substituent (**IM19**  $\rightarrow$  **TS19-20** in Fig. 6). That is, under the given conditions, with cyclopropyl substitution, the obtained *Z*-configured enone cannot isomerize further into the *E*-configured enone. In order to explain this fact, we compared the geometric parameters of four key stationary points, including **IM9**, **TS9-10**, **IM19** and **TS19-20**. As seen in Table 1, the  $\angle C^1-N-C^6$  changes from 120.4° in **IM9** to 130.7° in **TS9-10**. By comparison, for **IM19** to **TS19-20**, the corresponding bond angle varies insignificantly (128.5° vs 128.1°). It is likely that, to ensure the  $C^6=C^7$  bond rotation, the bulky cyclopropyl group has to undergo a large structural twisting, which, as a result, produces an additional energy penalty in **TS9-10** and results in **<sup>Z</sup>P<sub>a</sub>** as the final product.

**Fig. 7.** Noncovalent interactions analyses for the chemoselectivity-determining TSs with cyclopropyl substituent (left column), optimized geometries for the chemoselectivity-determining TSs with H substituent (right column), as well as the Gibbs free energies, electronic energies ( $\Delta E$ ) in parentheses and entropy effect ( $-T_{298K}\Delta S$ ) in square brackets in DCE solvent of the four TSs involved (marked with blue color). L = IPr

**Table 1.** Optimized geometrical parameters of **IM9** and **TS9-10** in Fig. 3, and **IM19** and **IM20** in Fig. 5. The bond distances and bond angles are given in Å and°, respectively. L = IPr

<b>IM9</b>	→	<b>TS9-10</b>	<b>IM19</b>	→	<b>TS19-20</b>
					
C7=C8 = 1.391		C7-C8 = 1.463	C7=C8 = 1.407		C7-C8 = 1.468
C7-N = 1.381		C7-N = 1.317	C7-N = 1.354		C7-N = 1.311
∠C6-C1-N = 121.2°		∠C6-C1-N = 123.4°	∠H-C1-N = 120.6°		∠H-C1-N = 120.6°
∠C1-N-C7 = <b>120.4°</b>		∠C1-N-C7 = <b>130.7°</b>	∠C1-N-C7 = <b>128.5°</b>		∠C1-N-C7 = <b>128.1°</b>
∠N-C7-C8 = 129.5°		∠N-C7-C8 = 123.4°	∠N-C7-C8 = 132.7°		∠N-C7-C8 = 130.8°

Overall, the substituent-induced divergent chemoselectivity originates from a combination of  $O\cdots H-N$  hydrogen bonding interaction and ease of rotation of the  $C^6=C^7$  double-bond. In the cyclopropyl system, the hydrogen bonding interaction enhances the stability of **TS6-7** leading to *Z*-configured enone, which is the final product due to large structural distortion caused by the bulky cyclopropyl group. With the H substituent, the presence of the hydrogen bonding interaction forces the structure of **TS16-17** to be strained, resulting in a decrease in order ( $\Delta S$ ). And ultimately, the *E*-configured enone is formed exclusively.

According to the calculated results above, we schematically display the integral catalytic cycles for the formation of **<sup>Z</sup>P<sub>a</sub>** and **<sup>E</sup>P<sub>b</sub>**, respectively, in Scheme 3, which provides a consistent view of the mechanistic details for the annulation reactions with H- and cyclopropyl-substituents.

**Scheme 3.** A sketch of the catalytic cycles for forming  $ZP_a$  and  $EP_b$  from the Au(I)-catalyzed annulations of cyclopropyl- and H-substituted 1,4-diyn-3-ols with isoxazole **B**, respectively, based on the present calculations. L = IPr

#### 4. Conclusions

The Au(I)-catalyzed [4+1] annulations of isoxazole (**B**) with cyclopropyl- and H-substituted 1,4-diyn-3-ols (i.e., **1A** and **2A**), respectively, have been computationally evaluated. Both reactions are initiated by  $LAu^+$   $\pi$ -coordination to facilitate the N-nucleophilic attack of isoxazole **B**. A theoretical study indicates that the preferred nucleophilic position at non-phenylalkyne moiety over phenylalkyne moiety can be inherently attributed to the larger steric crowding involved in the N attack towards the phenylalkyne site.

After the nucleophilic attack, a concerted three-step forward product, obtained by

simultaneous isoxazole O-N cleavage, 1,2-phenylalkyne shift and the hydroxyl H shift was identified as a key intermediate, rather than the experimentally proposed iminogold carbene species. With the hydroxyl H migration to the N atom, the resultant nitrogen-hydride species favorably evolves either into  $^Z\mathbf{P_a}$  for the **1A** system via  $\text{C}^1=\text{C}^2$  rotation  $\rightarrow$  nucleophilic cyclization  $\rightarrow$  **B**-assisted protodeauration or into  $^E\mathbf{P_b}$  for the **2A** reaction via two C=C rotations  $\rightarrow$  nucleophilic cyclization  $\rightarrow$  **B**-assisted protodeauration. Further theoretical investigations indicate that the chemoselective step is the nucleophilic cyclization but not the C=C double-bond rotation. The chemoselectivity for formation of  $^Z\mathbf{P_a}$  can be explained as follows: (i) the additional  $\text{O}\cdots\text{H}-\text{N}$  hydrogen bonding interaction helps to stabilize the cyclization transition state **TS6-7** leading to  $^Z\mathbf{P_a}$  and (ii) a big structural deformation generated in the  $^Z\mathbf{P_a} \rightarrow ^E\mathbf{P_a}$  isomerization significantly increases the distortion penalty and thus leads to  $^Z\mathbf{P_a}$  as the sole final product. In contrast, for the **2A** reaction, the chemoselectivity is reversed to provide the *E*-configured enone  $^E\mathbf{P_b}$ . It was found that the strained structure in the selective-controlled **TS16-17** leading to  $^Z\mathbf{P_b}$  orders the system, which enables **TS25-26** to be lower in free energy than **TS16-17** and consequently results in the exclusive formation of  $^E\mathbf{P_b}$ .

The present theoretical results provide in-depth insights into the mechanisms and origins of regioselectivity and chemoselectivity of the title reactions and rationalizes the experimental observations.
